*The present research has been conducted within the project “Productivity, Non-Tariff Measures and Openness” (PRONTO) funded by the European Commission within the Seventh Framework Program grant agreement 613504. We are grateful to the CompNet network for producing and giving us access to the data.

Abstract

In this paper, we explore how tariff and Non-Tariff Measures (NTMs) introduced by the EU are related with market conditions in domestic EU markets. While Tariffs work as a pure tax on import, NTMs potentially affect costs of both domestic firms and foreign exporters. NTMs may not necessarily work as protectionist measures and even induce pro-competitive effects in the domestic market in the longer term, especially if we allow for firms mobility. The impact could be different for large and small firms. We extend the model by Melitz and Ottaviano (2008) to include Non-Tariff barriers. We derive some testable implications relating Non-Tariff barriers to the number of firms selling in the domestic market, the share of exporters, and average efficiency. We then take the model to the data for a group of European countries and manufacturing industries. We combine Compnet data for 15 EU countries in 2001-2012, providing information on firms performance at the industry level and by size class, with the STC WTO-I-TIP database, with information on Specific Trade Concerns raised at the WTO on NTMs and with the Trains database with information on Tariffs. We find that the link between NTMs and domestic market conditions depends on whether they involve new standards and technical specifications imposed on both domestic and foreign firms, or, rather, the extension to foreign firms of standards and technical specifications already adopted by domestic firms. In the first case, we observe a decline in the number of firms, in average productivity and in the export share; in the second case we observe procompetitive effects: an increase in the number of firms, of average productivity and of the share of exporters. Tariffs have similar effects as in the second NTMs case, albeit of a larger magnitude. These results are consistent with a theoretical framework allowing for firms mobility in the longer term.

1 Introduction

Non-Tariff Measure (NTMs) are generally analysed with respect to their impact on trade, and their being protectionist measures. In this paper, we take instead the perspective of domestic producers and look at the effects of NTMs on market conditions in the domestic economy of the country imposing them and on their exporters. We do this in theory and then for a sample of European countries and industries, analysed between 2002 and 2015.

From the perspective of domestic firms there is a crucial difference between tariffs and NTMs. Tariffs work as a pure tax on import, and induce a cost wedge between domestic and foreign exporters. NTMs may potentially affect the costs of both domestic firms and foreign exporters. In other words, domestic firms must adopt the same standards and technical requirements of foreign firms. Consequently, the cost of NTMs is levelled for both domestic and foreign exporters. As discussed in the literature reviewed in the next section, there are two different scenarios that should be considered. In the first case the standard or the technical requirement is new for both sets of firms. Also, domestic ones must adopt it from scratch. The second case, refers to standards already adopted by domestic firms that are extended to foreign exporters. Even though this measure only imposes a cost on foreign exporters, it is not necessarily discriminatory, as it forces foreign exporters to level their production conditions to those of domestic firms. Still, it may rebalance the competitive advantage and discourage foreign exports, similarly to tariffs.

In what follows we develop a theoretical framework to analyze these three different options, (i) the introduction of a tariff, (ii) the adoption of a new NTM by domestic firms and foreign exporters, (iii) the extension of an already domestically adopted NTM to foreign exporters. We work within the framework of the model by Melitz and Ottaviano (2008), Section 3. We derive some testable implications relating Non-Tariff barriers to the number of firms selling in the domestic market, the share of exporters, and average efficiency.

The theoretical analysis envisages a long-term framework; therefore, it also allows for firms mobility between the two hypothetical identical countries analysed, country A (domestic) and country B (foreign). Trade barriers jumping is frequently observed in large markets like the European Union, think at Japanese automobile producers in the UK. This is more likely with tariffs, but also with NTMs, because of specialization and of the gains from avoiding two different technical standards on the same production line.

We identify the following results for domestic firms. The introduction of a new unilateral NTM on both domestic and foreign firms, reduces the number of firms producing in the domestic market, the share of exporters and average productivity. This is a long-term result. In the short term (not analysed) the increased cost of producing at home implies that the number of domestic firms decline, as the least efficient ones exit. There might be fewer foreign exporters also. In the longer term, the number of firms based in A will decline further because of mobility. Producing in B is now more convenient, as the standard is not imposed on domestic sales there. The firms that will move to B will be the most efficient ones (which can afford the cost of relocation). The combined effect of the exit of domestic firms and possibly of the decline of foreign exports from B, will increase the market share of the remaining domestic firms and hence raise the minimum cost cut off. These counterbalancing effects introduce ambiguity, and will in the end generate a decline in average productivity, with smaller less productive firms re-entering the market and also a decline in the share of exporters.

The introduction of a unilateral NTM affecting only foreign firms (as domestic ones have already introduced it) has opposite effects. Here, the number of domestic firms increases. Also, as the relative cost of producing abroad is now higher, exporters from B to A will relocate in A. As generally these are the most efficient firms, both average productivity and the share of exporters will increase in the domestic market A. The second case (NTM only on foreigners) gives identical theoretical predictions than the inclusion of a tariff, though likely of lower magnitude

Note that these long term outcomes partly contradict short term expected effects. In the first case, the introduction of the NTMs by both domestic and foreign firms should have pro-competitive effects, leading to exit of the least efficient domestic firms and consequently to an increase in average productivity. In the second case the NTM works as a sort of protectionist measure, with anticompetitive effects: entry of least productive domestic firms and decline of average productivity. It is only the longer term relocation of firms that reverts these two results. In the end we have less firms, but lower average productivity in the first case, and more firms, but higher average productivity in the second case.

We then take the model to the data for a group of European countries and manufacturing industries. We combine CompNet data for 16 EU countries in 2002-2012, providing information on firms' performance at the industry level and by size class, with the STC WTO-I-TIP database, providing information on Specific Trade Concerns raised at the WTO on NTMs, and with the TRAINS database providing information on Tariffs. The empirical analysis exploits

cross industry and cross-country heterogeneity in trade barriers (see section 3). Even though both NTMs concerned raised by foreign trade partners and tariffs are the same for all EU countries, their different trade structures make them differently affected by NTMs and tariffs.

In the empirical analysis (Sections 4, 5, and 6), we identify two types of NTMs. Technical Barriers to Trade (TBT) and Sanitary and Phyto-Sanitary (SPS) measures. In particular, by using data on STC raised to TBT and SPS committee, we consider those TBT and SPS that are perceived as trade barriers. We investigate the effects of these TBT and SPS and of tariffs on market conditions of the country imposing the measure, in terms of number of firms, share of exporters, and average productivity; we investigate whether and to what extent these effects are heterogeneous across firms, and therefore also affect firms' distribution.

Most empirical results confirm broadly the theoretical predictions. Interestingly we find that the domestic market effect for SPS is the one predicted by the first model of NTMs, whereby NTMs are new for both home and foreign firms. We find in fact that the number of firms decline, especially large more efficient firms. Yet, we do not find the predicted effect of a decline in the share of exporters.

As for TBT we find results consistent with the second model of NTMS, those regarding only foreign producers. Here, the number of firms increases, especially large firms and also average efficiency increases. Tariffs have similar effects of this latter case, as expected, yet of a larger magnitude. The effects on the share of exporter is instead opposite to what expected, as it declines instead of increasing.

These results will have to be confirmed by further analysis, in particular the obvious endogeneity problems between trade related measures and the home performance of domestic firms will have to be addressed in further extensions of this work.

2 Related Literature

A recent stream of literature investigates the role of standard-like NTMs, also called technical measures, namely, Sanitary and Phytosanitary Standards (SPS) and Technical Barriers to trade (TBT) ¹, with respect to trade flows and welfare.

¹SPS are measures affecting areas such as restriction for substances, restriction for non eligible countries' hygienic requirements, or other measures for preventing dissemination of diseases; all conformity assessment measures related to food safety, such as certification, testing and inspection, and quarantine; TBT are measure such as labelling, marking, packaging, restriction to avoid contamination or other measures protecting the environment, standards on technical specifications and quality requirements (Gourdon, 2014)

SPS and TBT are not introduced with a protectionist aim, at least not explicitly. Their scope is to increase the quality of goods and/or reduce informational asymmetries (Gourdon, 2014). Nonetheless, these measures could also hide the aim to build a barrier to trade. Moreover, even if welfare enhancing, restricting trade might be a side outcome, because costs of compliance might be different across countries, in particular developed and developing countries (Disdier et al., 2008; Marette and Beghin, 2010), and also within countries across heterogeneous firms (Fontagné et al., 2015).

Because of the potential trade reducing effects of NTMs, since 1995, the WTO agreements on TBT and SPS require members to notify information on their imposed measures for transparency. Then a Specific Trade Concern can be activated, when a member (ore more than one) raises a concern to the WTO according to which a specific measure is perceived as a barrier to exporting in the country imposing the measure.

For the fact that they are not introduced with protectionist aims, this per se' opening room for ambiguities and controversial assessments, TBT and SPS differ intrinsically from traditional trade barriers (Non-technical measures and tariffs)² in their economic implications along several dimensions, by working as potential supply and demand shifters (Beghin et al., 2015b; Fugazza, 2013). When standard-like NTMs imply a cost, e.g. to adapt the production process, to buy higher quality intermediate goods and inputs, to comply with the standard, typically both domestic and foreign firms bear this cost, while traditional barriers affect foreign firms only. But it could also be the case that domestic firms already met the standard in the country introducing the SPS/TBT measure, which would in this case have potentially discriminatory effects with respect to foreign firms. On the other hand, in a world of heterogeneous firms, better foreign suppliers might satisfy the standard at a lower cost than domestic ones or vice-versa (Beghin et al., 2015b; Marette and Beghin, 2010). In general, the effects on trade depend on the relative cost of compliance across countries.

Standard-like NTMs can work as supply shifter by increasing the quality of the good or input, but also by solving technical incompatibilities and/or easing trust in buyer-supplier relationships (Jouanjean, 2012), this increasing matching opportunities. Depending on the measure and on the characteristics of the industry involved, they can help solving information asymmetries, reducing transaction costs in buyer-supplier relationships along the global value chain. They

²Non-technical measures are the subset of measures under categories from D to P in the Unctad classification of NTMs (Gourdon, 2014).

can also increase costs, marginal of fixed, of compliance and/or they shift these costs from buyer to suppliers with potential advantages for large suppliers (Beghin et al., 2015b). The extent of the supply shift will depend on the measure and the industry involved, but also on the size and geographical location of the firm. According to Beghin et al. (2015b) the effect of NTMs along the global supply chain is country, sector and standard specific, in some cases favouring large suppliers, in some others small firms.

They can also work as (final) demand shifter (Sturm, 2006; Tian, 2003), increasing the willingness to pay of consumers by increasing or certifying the quality or safety of the good (Disdier and Marette, 2010), solving information issues (Liu and Yue, 2009; Xiong and Beghin, 2014). Again, small firms and/or firms located in the South may benefit more than large firms from complying with the standard.

In general, the protectionist effects of standard type NTMs are ambiguous both because of heterogeneity across foreign and domestic producers (Marette and Beghin, 2010), and because they can be instrumental to overcome market failures and reduce negative externalities (Beghin et al., 2015a). The evidence on the effects of NTMs on trade flows is actually mixed, the results showing both trade enhancing and trade restrictive consequences depending on the country pairs, on the sector and on the measure considered (Beghin et al., 2015a; Cadot and Gourdon, 2016; Carrere, 2011).

The introduction of a TBT or SPS measure can generate contrasting effects on firms' domestic and international activities. Moreover, since these effects are likely to be heterogeneous across firms of different size and productivity, the standard-like NTMs will also affect competition in the domestic market, with consequences on efficiency, prices and varieties availability.

Our work is related to three main stream of literature. The first one is the group of contributions assessing the potential protectionist effect of standard-like NTMs, by analyzing the relationship between NTMs and trade flows (Anders and Caswell, 2007; Disdier et al., 2008; Kee et al., 2009; Wilson and Otsuki, 2004; Xiong and Beghin, 2014).³ The firm level evidence looking at firms' exporting margins is usually focused on the effects of NTMs in destination markets on firms' exporting activities. Fontagné et al. (2015), using French custom data and STC on SPS show that both small firms and, to a lesser extent, large firms are negatively affected by NTMs measure in the destination markets (both along the extensive and the intensive

³For a comprehensive review on approaches and computation of NTMs see Beghin et al. (2015b) and Carrere (2011).

margin). The literature looking at the effects of standard-like NTMs in developing countries reach also mixed results, some of them showing an export enhancing effect for the firms, in particular large exporters, bearing the cost to meet the standard (Chen et al., 2008; Henson et al., 2011; Martincus et al., 2010; Otsuki, 2011), others finding a negative effect for firms' exporting activities (Schuster and Maertens, 2015). Cadot and Gourdon (2016) looks instead at the effects of NTMs on the price of imported goods and the role of regional trade agreements as mediating factors in the relationship between NTMs and prices.

A second group of contributions indirectly related to our work investigates the effects of NTMs on the labour market in the country imposing the standards (Leonardi and Meschi, 2017) or in the country specialized in exporting a good on which a standard has been imposed by trade partners (Colen et al., 2012).

Our work is also related to the heterogeneous firms' stream of literature, where the effects of variations in trade policy on firms and productivity depend on the type of trade costs affected and theoretical setup. In the standard CES model with heterogeneous firms (Melitz, 2003), an (symmetric) increase in the iceberg trade costs or fixed costs generate a similar outcome: an increase in the number of domestic producers and a reduction in the aggregate productivity. However empirical evidence suggests that changes in trade costs have heterogenous effects across firms with different size. For example, Nataraj (2011) finds that trade liberalization in India increased the average productivity of the firms at the top of the distribution.⁴

The removal of standard assumptions, such as CES, generates additional insights. Introducing heterogeneous demand elasticities, Spearot (2013) shows that imported varieties with high elasticity are the most harmed by an increase in tariff while low elasticity varieties not.⁵ Using indirectly additive preferences, Bertolotti et al. (2017) provide evidence that small firms are more harmed by an increase in the iceberg trade cost, compared to large firms.

Heterogeneity arises also from different trade costs (additive or multiplicative). Irarrazabal et al. (2015) provide evidence that the introduction of an additive import tariff is more harmful (in term of welfare and trade) than the corresponding multiplicative tariff.

In general, assumptions on consumers preferences and the characteristics of trade costs are crucial to define the effects of changes in the trade policy.

⁴Mion and Zhu (2013) show that an increase in the import competition from China in WTO did not reduce the survival probability of Belgian firms.

⁵Similarly to our model, Spearot (2013) assumes that consumer preferences are quasi-linear as in Melitz and Ottaviano (2008).

3 Theoretical Model: Non tariff Measures: Regulatory Standards

3.1 Closed Economy

We use the model in Melitz and Ottaviano (2008). (henceforth M-O). The closed economy is characterized by a continuum of firms, each one producing a single variety of a product, with cost function $C(q) = cq$, where c is specific to each firm, and results after a firm has decided to enter the market, from a random draw by Nature. Firms with too high a cost, in a sense to be specified later, will have to exit after entry. The demand function to each firm is derived by a quasi-linear utility function $U = q_0 + \alpha \int q_i di - \frac{\gamma}{2} \int (q_i)^2 - \frac{\eta}{2} (\int q_i di)^2$, where all the integrals are defined over the space of available varieties, q_0 is a *numeraire* good, q_i is quantity of variety of a differentiated good with index i , while γ measures the degree of product differentiation among varieties. The maximum price is a function of the utility function parameters and of the size of the country if in autarky and of the two countries under free trade. The inverse demand function is of the form $p_i = \alpha - \gamma q_i - \eta Q^c$, where $Q^c = \int q_i di$. The maximum price p^{\max} is a function of the utility function parameters and of the size of the country - if in autarky - and of the two countries under free trade. The resulting per-firm profit function in a closed economy is $\pi(c) = (L/4\gamma) (c_D - c)^2$ where L is the population size and $c_D = p^{\max}$ is the cut-off cost for surviving firms. The support of c is $[0, M]$, the distribution is assumed to be Pareto, namely $G(c) = (c/M)^k$ over $[0, M]$. Let $w \equiv c_D$ be the cut-off cost, then under the assumption of a Pareto distribution, and letting $\omega(L) = \frac{kL}{4\gamma M^k}$ the expected profit from entry is a linear transformation of

$$I(c, w) \equiv \int_0^w (c - w)^2 c^{k-1} dc, \quad (1)$$

Then, expected profit is

$$E(\pi) = \omega(L) \int_0^w (w - c)^2 c^{k-1} dc \quad (2)$$

A firm has to pay an entry cost f to enter the market and this cost is sunk after entry. Ex-ante entry is profitable only if expected profit is non-negative and in the long run entry shall occur till the expected profit from entry is zero, or till $E(\pi) = f$. Let $E(\pi) = f$, then (2) provides a

solution for the cutoff cost:

$$(c_D^0)^{k+2} \equiv 2(f/L)M^k\gamma(k+2)(k+1). \quad (3)$$

If a standard leads to a marginal cost increase equal to s the support of the cost distribution is translated from c to $q \in [s, M+s]$ where $q = c + s$. The cut-off now must satisfy $q = p^{\max}$; or $c_D + s = p^{\max}$. The distribution is $G(q) = ((q-s)/M)^k$. The zero profit condition before entry becomes:

$$E(\pi|s) = \omega(L) \int_s^z (z-q)^2(q-s)^{k-1}dc = \frac{L}{2\gamma M^k} \frac{(z-s)^{k+2}}{(k+2)(k+1)}. \quad (4)$$

Since z is the cutoff in the shifted support then $c'_D = z - s$ is the cut-off in terms of the base (or "identity") variable c . Inspection of (4) reveals that setting $E(\pi|s) = f$ implies a solution such that $z - s = c_D$, where c_D is the original value. Hence the new cost cutoff is equal to the original one⁶ plus s . The after-entry profit however is reduced for each firm. This makes entry less attractive ex-ante, leading to a reduction of the number of entrants in the industry. The lower number of entrants allows p^{\max} (and hence the cutoff cost) to increase. Average price is increased so that a lower quantity of the differentiated good is bought at equilibrium - while consumer will buy more of the numeraire good. The number of firms operating in the industry will decrease, as from Equation 13 in M-O, namely $N_s^0 = 2(k+1)(\gamma/\eta) \frac{(\alpha-c_D)/c_D}{c_D}$, due to an increase in the cutoff from c_D to $c_D + s$.

It is important to consider here that we are not allowing the standard to increase α , namely the utility of the differentiated good. In that case the result on the cut-off and on the numeraire would be ambiguous.

3.2 Open Economy.

In an open economy the introduction of a standard will raise costs for the home firms but it will also increase costs to foreign exporters. Country A, where the standard is introduced, will be less attractive as a location for production, but country B now is also affected because exports to A from B are more expensive than before the standard. Therefore the question is whether the increase in the cut-off cost for the home country hurts production and efficiency in A or B, and what are the effects on trade flows. The answer will clearly depend also on the effect

⁶The integral in (4) is also equal to $\omega(L) \int_0^{z-s} (z-s-c)^2(c)^{k-1}dc$

of the standard on the cutoff cost of country B. Let c_X^A represent the cutoff cost for the firms based in A exporting to B. Due to export costs of the iceberg form a unit exported arrives in country B with weight less than 1 hence the cost of a unit carried to country B from A is $\tau_B \cdot c$ where $\tau_B > 1$ (respectively τ_A for exports in the reverse direction). One can interpret the τ 's as incorporating tariff and transportation costs. To survive in country B an exporter from A must have cost at most equal to $c_X^A \equiv c_D^B / \tau^B$ (symmetrically $c_X^B \equiv c_D^A / \tau^A$). Letting $\lambda = \frac{k}{4\gamma M^k}$. The zero expected profit condition before entry is:

$$L^A \int_0^{c_D^A} (c_D^A - c)^2 c^{k-1} dc + L^B (\tau_B)^2 \int_0^{c_X^A} (c_X^A - c)^2 c^{k-1} dc = f/\lambda, \quad (5)$$

or,

$$L_A (c_D^A)^{k+2} + L_B (\tau_B)^2 (c_X^A)^{k+2} = \gamma\phi \quad (6)$$

where $\phi = 2(k+1)(k+2)M^k f$. Then, using the equalities $c_X^i = c_D^j / \tau^j$ and letting $\rho_i = 1/\tau_i$ for $i = A, B$ one obtains a system of two equations in two unknowns:

$$\begin{aligned} L_A (c_D^A)^{k+2} + L_B \rho_B (c_D^B)^{k+2} &= \gamma\phi \\ L_B (c_D^B)^{k+2} + L_A \rho_A (c_D^A)^{k+2} &= \gamma\phi \end{aligned}$$

whence the solutions c_D^{A0} and c_D^{B0} satisfy:

$$(c_D^{A0})^{k+2} = \frac{\gamma\phi}{L_A} \frac{1 - \rho_B}{1 - \rho_A \rho_B} \quad \text{and} \quad (c_D^{B0})^{k+2} = \frac{\gamma\phi}{L_B} \frac{1 - \rho_A}{1 - \rho_A \rho_B}.$$

3.3 Marginal-cost-increasing standard

Let c in $[0, M]$ define the *identity* cost for firm c . Firms with identity cost $c > z - s$ will exit after entry, where z is the cut-off under the support shift ($z = c_D + s$). Let $u_j = c_D^j - s$ for $j = A, B$ and $w_j = c_X^j - s$. Let $h = \left(\frac{k}{4\gamma M^k}\right)^{-1} f$, then the zero expected profit conditions⁷ write as:

⁷In terms of the integrals like in (1) they are:

$$\begin{aligned} L^A I(c, u_A) + L^B (\tau_B)^2 I(c, w_B) &= h \quad (A) \\ L^B I(c, u_B) + L^A (\tau_A)^2 I(c, w_A) &= h \quad (B) \end{aligned}$$

$$L^A (c_D^A - s)^{k+2} + L^B (\tau_B)^{-k} (c_D^B - s)^{k+2} = \gamma\phi \quad (\text{a})$$

$$L^B (c_D^B)^{k+2} + L^A (\tau_A)^{-k} (c_D^A - s)^{k+2} = \gamma\phi \quad (\text{b})$$

where $c_X^A - s = \frac{c_D^B}{\tau_B} - s$ and $c_X^B - s = \frac{c_D^A}{\tau_A} - s$.

Although an analytical solution is hard to find due to the term $(c_D^B)^{k+2}$ in the second equation we can state:

RESULT 1: *An increase from zero to $s > 0$ of marginal cost due to a standard in the home country raises the cutoff cost $c_D^A - s$ defining the identity of firms that makes zero profits after entry in Home. It raises the domestic effective cut off cost z by an amount larger than s . It decreases the cutoff cost in the foreign country, and it also decreases the cut off for exporters in B.*

In Home the competitive pressure decreases leading to a lower number of entrants and of surviving firms, and to a lower average productivity. The average price in country A (home) increases⁸. Furthermore,

RESULT 2: *The proportion of exporters from the home country decreases.*

PROOF: The ratio $G(c_X^A - s)/G(c_D^A - s)$, namely the proportion of exporters in the Home country is the ratio $((c_D^B/\tau_B) - s)^k / (c_D^A - s)^k$. The effect of an increase in s on the numerator is negative while that on the denominator is positive. Q.E.D.

By the same token, the proportion of exporters in the foreign country increases. The number of firms selling in country A, N^A , decreases since it is given by $N^A = \frac{2(k+1)\gamma}{\eta} \frac{a-z}{z}$. By the same token, N^B increases. The number of entrants in country A also decreases. It is given by:

$$N_E^A = \frac{M^k}{1 - \rho^A \rho^B} \left[\frac{N^A}{(c_D^A - s)^k} - \rho^A \frac{N^B}{(c_D^B)^k} \right],$$

and hence it decreases since the first ratio in square brackets decreases and the second increases. Finally, the number of firms located in A that survive, $G(c_D^A - s)N_E^A$ decreases. Therefore we can state:

Proposition 1 (summary for effects of a standard in Home): *A standard that raises marginal*

⁸It is given by $\tilde{p}_A = \frac{2k+1}{2k+2}(c_D^A + s)$.

costs - and does not raise the utility of the good - has the following long run effects: the profitability of locating in the home country vis-a-vis the foreign country decreases, hence the number of entrants in the home country decreases. The maximum price at which the good is sold increases and hence so does the cutoff cost for a firm located in A. The number of firms selling in A decreases, the number of firms located in A decreases, and so does the proportion of exporting home firms. The average marginal cost increases. The support of the distribution of costs is wider. The average price increases.

3.4 Tariff

A marginal cost increasing standard imposed by country H is different from a tariff because a tariff, t , is paid only by the foreign firms. The profit of the foreign exporter is changed to $\pi_X^B(c, t) = (L^A/4\gamma) (\tau_A)^2 (c_D^A - t - c)^2$.

Setting $\tau_A = 1$ be the original iceberg cost for A, to simplify, the new iceberg cost τ'_A such that delivered cost $\tau'_A c = c + t$; then $\tau'_A = \frac{t}{c} + 1$ varies inversely with c . This is a slight modification with respect to M-O, who only consider direct changes in τ_B , however this has no consequence on the main results.

Only firms in B with costs $c < c_D^A - t$ can export to A hence the population of foreign exporters is, regarding their identity cost, more efficient than before the tariff, but the tariff offsets this cost advantage and their average price increases. The cut-off costs are given by the solutions to:

$$\begin{aligned} L^A (c_D^A)^{k+2} + L^B (\tau_B)^{-k} (c_D^B)^{k+2} &= h \quad (\text{At}) \\ L^B (c_D^B)^{k+2} + L^A (\tau_A)^{-k} (c_D^A - t)^{k+2} &= h. \quad (\text{Bt}) \end{aligned}$$

It is straightforward to show that:

RESULT 4: *The cutoff cost for the home country decreases after a per-unit tariff is unilaterally introduced by the same country.*

An increase in the tariff is equivalent to a decrease in ρ_A . The cut off costs c_D^A is decreased since ρ_A is decreased. By contrast the cut off costs c_D^B is increased. Then we can follow M-O on this account. The number of entrants in A increases, while in B decreases.

The number of sellers in country home (A) increases and in B decreases.

RESULT 4 : *The proportion of exporters from A to B $G(c_X^A)/G(c_D^A) = G(c_D^B/\tau_B)/G(c_D^A)$ increases.*

The number of sellers in country A may increase or decrease: $N^A = G(c_D^A)N_E^A + G(c_X^B)N_E^B$ is a sum of two terms with size depending upon, among other things, the size of the two countries. For the same reason, since the imported products in A will be sold at a higher price than before the tariff, the net effect on average price of goods sold at home is ambiguous.

Proposition 2 (summary for effects of a tariff in Home): *A unit tariff has the following long-run effects in home: the profitability of locating in the home country vis-a-vis the foreign country increases (protectionist effect), hence the number of entrants in the home country increases. The maximum price at which the good is sold decreases and hence so does the cutoff cost for a firm located in A. The number of firms selling in A increases, the number of firms located in A increases, and so does the proportion of exporting home firms. The average marginal cost decreases. The support of the distribution of costs is narrower. The average price decreases.*

3.5 Standards that "follow" already adopted practices

If firms regulators impose standards that are already largely adopted by the home firms, the cost increase will be felt only by a portion of the home firms, but by all the foreign firms. An extreme situation is one where all the home firms have already adopted the standard before it becomes mandatory. This is also the easiest situation to analyze.

If there is no cost increase in home, then equation (a) above is unchanged while that for the foreign country becomes:

$$(B') \quad L^B (c_D^B)^{k+2} = h - L^A (\tau_A)^{-k} (c_D^A - \tau_A s)^{k+2}.$$

This can be used to rewrite (a) as:

$$L^A (c_D^A)^{k+2} + (\tau_B)^{-k} \left[h - L^A (\tau_A)^{-k} (c_D^A - \tau_A s)^{k+2} \right] = h.$$

By differentiating this equation one obtains:

$$\frac{dc_D^A}{ds} \left[(c_D^A)^{k+1} - (\tau_A \tau_B)^{-k} (c_D^A - \tau_A s)^{k+1} \right] = - (\tau_A \tau_B)^{-k} (c_D^A - \tau_A s)^{k+1},$$

hence $(dc_D^A/ds) < 0$, where the sign follows from the positive sign of the term in square brackets. Furthermore one can show⁹ that $(dc_D^A/ds) > 0$, so that all the results concerning the effect of a standard are reversed if compared with the case of a marginal cost increasing standard of Proposition 1.

Hence the asymmetry in the impact of a standard, when it only affects the foreign firms, reverses the sign of the effect on the cutoffs for the home and foreign country. All the performance indicators will vary in the same direction as for a tariff and opposite to the change of a standard that involves an increase in marginal cost equal at home as abroad. Furthermore one can infer what follows: let s^i , for $i = A, B$, denote the marginal cost increase implied by the standard in country i ; imagine that $\Delta s \equiv s^B - s^A \geq 0$, then for Δs larger than some threshold value, the results would be in the same direction as those of a tariff as in Proposition 2. While, for $s^A = s^B$ and by continuity for Δs smaller than the threshold value, the results would be those of Proposition 1. One can also speculate that the intensity of the changes will be small for small values of Δs in a neighbourhood of the threshold value.

Summing up, if there is a substantial difference in the cost burden implied by the standard in favour of the home country firms, the changes in the number of firms, productivity, and fraction of exporters will be in line with those of a tariff. The results will be reversed only for standards leading to cost increases that are close enough across countries.

4 Data

We combine three major data sources. First, we use a database on specific trade concerns (STC) raised to TBT and SPS committee at WTO. Second, we consider the average applied tariff using the database from TRAINS. Finally, we retrieve information on market condition using CompNet, a recent database on aggregate statistics computed from firm-level data.

4.1 Non Tariff and Tariff Barriers

The first data source is the STC database on the Non Tariff Measure (NTM) notifications to the WTO from the Integrated Trade Intelligence Portal (I-TIP). It includes relevant information from TBT and SPS committees (Ghodsi et al., 2015).¹⁰ These two committees provide a

⁹Write $L^B (c_D^B)^{k+2} - h = -L^A (\tau_A)^{-k} (c_D^A - \tau_A s)^{k+2}$ and take logarithms. Then differentiate to get the result, given that $\frac{dc_D^A}{ds} < 0$ has been proven already.

¹⁰TBT product requirements established by governments with the objective to protect human health and safety, environment, or quality. SPS measures aims at ensuring food safety, and preventing the spread diseases among

platform to WTO members to settle issues related to regulation on product standards, in order to avoid discriminatory practices that create unnecessary obstacles to trade. Both TBT and SPS standards have to be notified to WTO and are applied to both domestically produced and imported goods. Notifications apply to existing or in the pipeline norms. If a TBT or a SPS measure create "an unnecessary obstacles to trade", one or more WTO member states may raise a concern to the committees in order to ask the removal of the measure. Therefore, when a specific TBT or SPS measure is perceived as an obstacle to trade, a concern is raised (See section A for more details).

The STC database records both countries that raise the concerns, the country which imposes the standard, and the product covered by the measure (both TBT or SPS). The STC database reports information at HS6 digit level so we use products and HS-6 digit as synonymous. Finally, the STC database includes the year in which the concern has been raised and whether it has been resolved.¹¹ Therefore, when a country raise a concern over a measure, it suggests that this specific measure is perceived as an effective barrier to trade. A product is protected by a NTM if a concern has been raised and not resolved: in that case we consider a specific good covered by a NTM (see Section 4.3).

Another source on non-tariff trade measure is TRAINS. However this source has two main drawbacks. First, NTMs from TRAINS are not updated since 2001 so that this source is not compatible with CompNet (see section 4.2). Second, TRAINS records NTM without mentioning if a specific regulation is as a barrier to trade or not: such information is retrieved through a survey on exporters perceptions of obstacles to foreign-market access. Therefore, we prefer to use WTO STC database.

The STC database is merged with tariff data from TRAINS database. The tariff dataset includes information on the effectively applied tariff (AHS) at HS-6 digit level for each year and country pairs.¹² Finally, we merge STC and tariff data using HS-6 digit classification. To be consistent with our empirical analysis, we consider European Union (in STC and tariff data) as the importing country which imposes a tariff or set a TBT or SPS measure.

animals and plants.

¹¹In most of the cases concerns are closed with a gentlemen agreement between parts (Fontagné et al., 2015). As a rule of thumb, we consider closed a concern after two years. Results are unaffected if we use a period of three years.

¹²The effectively applied tariff is defined as the lowest available tariff. If a preferential tariff exists, it will be used as the effectively applied tariff. Otherwise, the Most Favourite Nation tariff will be used.

4.2 CompNet

Under the coordination of the European Central Bank, 17 national central banks ¹³ have produced a set of harmonized and comparable sector-year level indicators based on national firm-level samples (Lopez-Garcia and di Mauro, 2014).¹⁴ For each triple NACE rev.2-2 digit sector, country, and year, the indicators available are, among the others, number of firms, number of exporting firms as well as other information such as average labor productivity or employment level.

CompNet comprises two different samples. The “*full sample*” is produced from countries’ samples based on firms with at least one employee and covers the period 1995-2012, while the “*20E sample*” is restricted to firms with at least 20 employees and covers the period 1995-2012.¹⁵ However, the “*20E sample*” ensures a relatively higher degree of representativeness (CIT) because the “*full sample*” in some cases do not cover smaller firms (those with less than 10 employees in Poland, less than 20 employees in Slovakia, less than 750,000 euros of turnover in France), and in the other cases tend to be biased towards medium and large firms (such a bias is severe for Austria and Germany). To improve representativeness and homogeneity across countries, the “*20E sample*” has been enriched by a weighting scheme based on the total number of firms by country-year-sector-size class taken from Eurostat Structural Business Statistics (SBS). Thus, “*20E sample*” is the most appropriate database for cross-country analysis.

4.3 Protection Index

In order to merge STC-Tariff database with CompNet, we need to construct indicators of protection with both tariff and non tariff measure which are defined at country (CompNet), sector (Nace rev2-2 digit), and year level. The computation of a protection index raises two concerns. First, CompNet data are disaggregated at country (sector) level while trade protection, in particular for NTM, is common across the European Countries. Second, HS nomenclature has to be aggregated at Nace Rev.2-2 digit.

To harmonize nomenclatures, we use correspondence tables from the World Integrated Trade Solutions (WITS) and RAMON-Eurostat databases. In order to identify HS-6 digit products

¹³Austria, Belgium, Croatia, Estonia, Finland, France, Germany, Hungary, Italy, Malta, Lithuania, Poland, Portugal, Romania, Slovakia, Slovenia, and Spain. We are going to use in the current analysis the fourth release.

¹⁴The unit of analysis is the firm. Self-employed (physical persons with economic activity) are generally not included.

¹⁵Both samples are slightly unbalanced: for example, Portugal data begin in 2006, while Belgian ones end in 2011.

within each Nace rev.2-2 digit, we proceed as follows. First we consider HS 2002 revision for STC and tariff database.¹⁶ Second, we use correspondence between HS2002 and HS2007, and between HS2007 and CPA2008. Once we have the correspondence between HS2002 and CPA2008, we could aggregate all HS2002-6 digit within the first two digits of CPA2008: first two digit of CPA 2008 corresponds to NACE re.v2-2 digit.

In order to compute the degree of protection (due to tariff or NTM) for each CompNet country c and sector s , we first define the average tariff imposed to extra-eu exporters for each CompNet country c , as follows

$$T_{js}^c = \sum_{p(s)=1}^{P(s)} t_{jp}^{EU} \frac{import_{jp}^{c2002}}{import_{js}^{c2002}} \quad \forall j \in s (NACE rev2 2d) \quad (7)$$

In Eq.7, j is the exporting country, i.e., China, s is the NACE rev2-2 digit sector, p is the product (HS-6 digit) that belongs to the NACE rev2, c is a CompNet country, and t_{jp}^{EU} is the tariff imposed by EU to product p from country j or the STC raised by country j against EU for a product p . Notice that, if we instead consider STC, the term t_{jp}^{EU} takes value of one if a concern has been raised by country j versus EU in product p , otherwise it is zero.

The EU protection measure (t_{jp}^{EU}) is redistributed across CompNet countries using specific weights which consider if a tariff (or STC) in product p from origin j can be relevant for country c . Using imports share, we measure if a good p accounts for a large quota of imports from origin j in sector s ; the second term in the r.h.s. of Eq.7 is defined by $import_{jp}^{c2002}$ and $import_{js}^{c2002}$ which are the imports of product p in country c from j and the total imports in sector s from j , respectively. Weights are constant over time and refer to 2002 to minimize endogeneity concerns.¹⁷

Finally, we compute the average protection (due to tariff or STC) for CompNet country c in sector s as

$$ProtectionIndex_s^c = \sum_{j=1}^J T_{js}^c \frac{import_{js}^{c2002}}{import_{tot,s}^{c2002}}. \quad (8)$$

Similarly to Eq.7, $ProtectionIndex_s^c$ is computed using as weights the relative share of imports from origin j to total imports, for a given sector s . We use in the empirical analysis (Section 5) $ProtectionIndex_s^c$ which is the overall average tariff imposed by country c in sector s

¹⁶In particular, HS2002 allows us to have the largest set of information for the period 2002-2012 (CompNet) both in terms of tariff, STC, and imports from a unique datasource

¹⁷Imports data are from WITS database. Imports are collected at HS-6 digit level.

to all extra EU imports. We can do the same construction for NTM (SPS and TBT separately).

4.4 Descriptive Statistics

We compute three indices of average trade protection as in Section 4.3. One index is defined with average tariff, while the second and third are defined using concerns on TBT and SPS.

Table 1 shows that average tariff is positively correlated with the two NTM index, while TBT and SPS seem not correlated among them. Trade flows are positively correlated with tariff and TBT, suggesting that most protected sectors are the ones more exposed to foreign competition (extra-EU).

[Table 1 about here.]

The protection index is usually higher for tariff than for TBT and SPS mainly for two reasons (see Table 2). First, most of the products within NACE rev2-2 digit are not subject to concerns¹⁸. On average 22 concerns are raised every year against the European Union, 16 TBT and 5 SPS. Consider that there are more than 5 thousands products registered every year so that in most of the cases TBT or SPS in Eq.7 takes value of zero. Most of SPS concerns are registered in Food (10) sector but some of them occur also in Wood (16), and Chemical (20) sector (Table 2). Conversely, TBT are spread more uniformly across sectors.

[Table 2 about here.]

Even if trade policy is common across European countries, the degree of protection seems quite heterogeneous across them (Table 3). Most protected countries by tariff (according to our index) seem Spain with Croatia, Poland, and Portugal. Conversely TBT seems to protect also France and Germany. Therefore, our protection index show some variability across CompNet countries (see Figure 1 and Figure 2).

[Table 3 about here.]

[Figure 1 about here.]

[Figure 2 about here.]

¹⁸Notice that goods under concerns are a subsample of products for whom a TBT or SPS notification exists. Notifications are a subsample of all existing products.

Finally, Figure 3 reports the time evolution of average protection (across countries and sector) for TBT and tariff. It is possible to observe that after 2007 there is a non-negligible increase in TBT while average tariff has decreased from 2005 to 2008. In the period of analysis, the average TBT protection is raised while, average tariff has decreased. We may observe a similar pattern for the weighted sum of the share of protected products (average across country sector is reported in Figure 4).¹⁹

[Figure 3 about here.]

[Table 4 about here.]

5 Empirical strategy

By using the STC data for both TBT and SPS built as described in Section 4.3, we investigate the relationship between NTMs and tariffs and market conditions in the EU countries imposing the measures. In particular, we consider the relationship between these measures and the total number of firms selling in the domestic markets, the share of exporters and the average productivity. According to the theoretical model developed in Section 3, we expect the (unilateral) introduction of a tariff to be positively associated with the number of domestic firms, the share of exporters and higher average productivity, As for NTMs, the theory predicts that the relationship between NTMs and market conditions depends on whether the standard is being introduced for the first time for both domestic and foreign firms, or rather, it is the extension to foreign firms of a measure already adopted by domestic ones. In particular, in the baseline case, where the (unilateral) introduction of the NTM implies an increase in the marginal cost for all firms, we expect a lower number of domestic firms, a lower share of exporters and lower average productivity, i.e. a worsening of market conditions in the country-sector imposing the measure.

When, instead, a country introduces a standard, which has already been adopted by a large number of domestic firms, the NTM works ‘like’ a tariff, since it represents a new cost only for foreign exporters to the country imposing the tariff. In this case, as for tariffs, we therefore should observe a positive relationship between NTMs, the number of firms, the average efficiency, and the share of exporters. We will also look at whether these effects are different along size and productivity distribution.

¹⁹Similar patterns have been observed by Fontagné et al. (2015).

For each measure, i.e., STC-TBB and STC-SPS, we investigate these relationships considering both an empirical model in which the measure is included alone and a model in which it is included together with the tariff.²⁰ We therefore start by estimating the following equations:

$$Y_{cst} = a_0 + a_1 \text{tariff}_{cst} + a_2 X_{cst} + u_c + u_s + u_t + \epsilon_{cst} \quad (9)$$

$$Y_{cst} = a_0 + a_1 \text{NTM}_{cst} + a_2 X_{cst} + u_c + u_s + u_t + \epsilon_{cst} \quad (10)$$

$$Y_{cst} = a_0 + a_1 \text{tariff}_{cst} + a_2 \text{NTM}_{cst} + a_3 X_{cst} + u_c + u_s + u_t + \epsilon_{cst} \quad (11)$$

where Y_{cst} , the dependent variables, are alternatively, the number of domestic firms, the share of exporters, the average labour productivity of country c in sector s at time t ; tariff_{cst} is the tariff barrier imposed by country c in sector s at time t as in equation 7 and NTM_{cst} are indicators of NTMs barriers, STC on either SPS or TBT, alternatively, as in equation 7 and equation 17; X_{cst} is a vector of other potential control variables; in particular, we include in all specifications the total import from EU27. u_c , u_s and u_t are country, sector and year fixed effects, respectively, and ϵ_{cst} an error term. The inclusion of country fixed effects allow us to control for all the unobservable country-specific persistent characteristics which might simultaneously affect the industrial structure, i.e. number of firms, share of exporters, efficiency, and the level of barriers, like institutional characteristics and quality, cultural inheritance and attitude towards competitiveness, geographical characteristics and resource endowments. The inclusion of sector fixed effects is useful in a framework where both the dependent and the explanatory variables are strongly related to both demand side and supply side industry characteristics; while year fixed effects allow us to control for both the business cycle and those macroeconomic events that might have happen in the period considered affecting simultaneously all EU countries.²¹ In all specifications both the dependent variable and the explanatory variables are in logarithm, and therefore the estimated coefficients can be interpreted as elasticities. We cluster standard errors at the country level and year to account for serial autocorrelation.

²⁰Otherwise we would clearly have an omitted variable problem since there might be several cases in which sectors at the two-digit level, which is what we consider, might be protected simultaneously by a tariff and a NTM, a case that cannot have a theoretical counterpart.

²¹For robustness we also estimate the same equation by including country-year and sector fixed effects, allowing us to capture all those observable and unobservable factors varying at the country-year level, like for instance gdp per capita, population, openness or country asymmetric business cycle. Results are shown in the Appendix D.

As a second step, we investigate whether the effects of the barriers might be heterogeneous depending on firms' size. We therefore investigate the previous relationships by interacting the barriers, both NTMs and tariffs, with a categorical variable obtained by splitting firms into three different classes on the basis of the employment.

We estimate the following equations:

$$Y_{cst} = a_0 + a_1szclass_{cst} + a_2tariff_{cst} + a_3szclass_{cst} * tariff_{cst} + a_4X_{cst} + u_c + u_s + u_t + \epsilon_{cst} \quad (12)$$

$$Y_{cst} = a_0 + a_1szclass_{cst} + a_2NTM_{cst} + a_3szclass_{cst} * NTM_{cst} + a_4X_{cst} + u_c + u_s + u_t + \epsilon_{cst} \quad (13)$$

$$Y_{cst} = a_0 + a_1szclass_{cst} + a_2tariff_{cst} + a_3szclass_{cst} * tariff_{cst} + a_4NTM_{cst} \\ + a_5szclass_{cst} * NTM_{cst} + a_6X_{cst} + u_c + u_s + u_t + \epsilon_{cst} \quad (14)$$

where $szclass_{cst}$ is the categorical variable built by splitting firms in three groups on the basis of their employment, namely: $szclass1$ (10-49), $szclass2$ (50-249), $szclass3$ (>249). The excluded group is $szclass1$, i.e. smaller firms.

6 Results

6.1 Tariffs, NTMs and the number of domestic firms

Table 5, where the dependent variable is the the number of domestic firms in logarithm, shows the estimates of the model in Eq. (9) (column 1), the estimates of the model in Eq. (10) (column 2 and 4,), the estimates of model in Eq. (11), in column 3 and 5.²² The results show a positive association between the tariff and the number of domestic firms in all the specifications, in line with what expected. The relationship is statistically significant at the 10% level when the tariff is considered alone (column 1) and with the TBT measure (column 5), while it is significant at 5% in the model with the SPS (column 3). In particular, an increase of 1% in the tariff is

²²See Table 12 in the Appendix D showing robustness with country by year and sector fixed effects.

associated with an increase of 0.003% in the number of firms (0.004% when SPS is included, as in column 3). These results are in line with the implication of the theoretical model, where firms relocate production in the country protected by the tariff.

Turning the attention to the NTM, we see that while the coefficients of TBT are in line with those of the tariff (0.004%), the results showing a positive and significant (at 1%) relationship with the number of domestic firms, the SPS measure is found to be negatively and significantly (at 5%) related with the number of firms. To an increase of 1% in the SPS measure corresponds a decrease of 0.004% in the number of firms (-0.005% when tariff is also included, column 3). This imply that the SPS measure is in line with the baseline case of our theoretical framework, where the standard is a new cost for all firms, both domestic and foreign, increasing their marginal costs. In this case firms find convenient to relocate production in the country where the standard is not imposed. On the other hand, the TBT measure behaves in line with the second cases that we consider in the theoretical model, where the domestic firms have already born the cost of the standard.

In general, our results suggests that NTMs can be related in various ways with the degree of competition in the market, in particular, according to our theoretical insights, depending on whether the measure was already met by domestic firms or not.

[Table 5 about here.]

Table 6 reports the results on the association between NTMs and the number of firms when taking into account the firm size class. As before, column 1 shows the results of the estimations of model 12, columns 2 and 4 those of estimations of model 13, while estimations of model 14 are reported in columns 3 and 5. In all models, i.e. both when considered alone (column 1) and when included with either SPS (column 3) or with TBT (column 5), the inclusion of a tariff is negatively and significantly related with the number of small firms, while it is positively and significantly related with the number of firms in larger size classes, in particular among the largest firms (>249). The relationship is statistically significant at 1% level when considered alone (column 1) and at 5% level when included with SPS (column 3) or TBT (column 5). In particular, when the tariff is included alone (column 1) an increase of 1% in the tariff corresponds to a decrease of 0.02% in the number of small firms and an increase of 0.017% and 0.054% in the number of medium firms and large firms, respectively. The magnitude of the coefficients is similar when the tariff is included with the SPS measure (column 3) or the TBT

measure (column 5). In line with the theoretical insights, the introduction of a tariff increases the competition in the market by inducing large-more productive firms to relocate production in the protected country, this negatively affecting small, less productive firms, which do not survive.

Columns 2 and 3 show results of opposite signs when looking at SPS barriers. In this case, the relationship between SPS and number of firms is positive and statistically significant at 1% level for small firms, while it negative and statistically significant at 1% level for largest firms. In particular, an increase of 1% in the SPS measure is associated with an increase of 0.014% in the number of small firms and a decrease of 0.024% in the number of large firms. The coefficients are slightly larger when including also the tariff (column 3), 0.02% and -0.032%, for small and large firms, respectively. The relationship is negative, but not significant for medium sized firms. These results again are in line with the implication of the theoretical model, which states that when a standard is introduced for all firms, both foreign and domestic, large firms may find convenient to relocate in countries not imposing the standard, this allowing small to survive in the domestic market.

Different evidence emerges when TBT are considered, as was the case in the aggregate analysis. In Table 6 we see that TBT are positively and significantly (at 5%) related with the number of largest firms, similarly to tariffs, while no relationship emerges in the other two size classes. In column 4 is shown that an increase of 1% in the TBT measure corresponds to an increase of 0.014% in the number of large firms (0.012% when tariff is also included, as in column 5). Therefore the relationship emerging in the whole sample, as described in Table 5, seems to be driven by the association between the TBT and the number of largest firms.

It is worth noting that the heterogeneity across size classes of the relationship of both NTM and tariffs with the number of firms, showing opposite signs depending on whether small or large firms are considered, helps explain the small magnitude of the coefficients (ranging from 0.003 to 0.005) in the results reported in Table 5 when size heterogeneity is not taken into account. Results by size class show that all these measures are associated with the number of firms in the country imposing the measure, but since these associations go in opposite directions in the different size classes, they partially offset when the class dimension is not considered.

[Table 6 about here.]

6.2 Tariffs and NTMs: implications for the share of exporters and efficiency

Turning the attention to the share of exporters as reported in Table 7 results are more mixed.²³ In particular, the share of exporters is positively, as expected, but not significantly associated with tariffs, while it is significantly and negatively related with the TBT measure. Moreover, it is not significantly related with the STC-SPS measure.

Some further investigation of the relationship between the measures of barriers and the share of exporters by size class helps understand the aggregate evidence.

As shown in Table 8, there is a positive association between the tariff and the share of exporters among small firms (significant at 10%), while the association turns to be negative and not significant for larger firms (column 1), this explaining the statistically insignificant relationship when potential heterogeneity across firm size classes is not considered. Similarly, as shown in columns 2 and 3, the SPS measure is negatively and significantly (at 1%) related to the share of exporters among smaller firms while the relationship turns to be positive (at 1%) among largest firms, the two contrasting effects canceling out in the whole sample. An increase of 1% in the SPS measure corresponds to a decrease of 0.014% in the share of exporters among small firms and to an increase of 0.022% in the share of exporters among large firms (column 2, and similarly in column 3 when the tariff is also included.) The TBT measure, in contrast, seems to be never significantly related to the share of exporters when analyzed by size class (columns 4 and 5).

[Table 7 about here.]

[Table 8 about here.]

Finally, we make an attempt to investigate the average efficiency, proxied by the labour productivity, in the whole sample (Table 9) and in both the population of domestic firms (Table 10) and the population of exporters (Table 11), separately.²⁴ The average productivity is positively and significantly associated with the TBT measure as expected from the implication of our theoretical model, while the relationship is not statistically significant in the case of the tariff. An increase of 1% in the TBT measure is associated with an increase of 0.006% in the average productivity. In our analysis so far has emerged that TBT barriers behave like tariffs. Therefore we expect them to increase the competition at the aggregate level showing

²³See Table 13 in the Appendix D showing robustness with country-year and sector fixed effects.

²⁴See Table 14 in the Appendix D showing robustness with country-year and sector fixed effects.

a positive association with the average efficiency. When we consider the SPS measure we find a positive and statistically significant relationship, even if half in magnitude with respect to the TBT case. This is apparently in contrast with the implication of our theoretical model. Nevertheless, splitting the sample into two groups, the population of domestic, not exporting, firms and exporters, we see that the positive relationship between SPS and efficiency survives in only one specification, namely, in the sub-sample of exporters when we do not include the tariffs (Table 11, column 1).

Besides, the absence of any statistical effect on productivity can be explained by the indicator we use. Labor productivity (i.e., value added per worker) or TFP include both pure technical efficiency and firms market power (see among others De Loecker et al. (2016); Forlani et al. (2016)). The former is a key variable of our model (efficiency is the inverse of marginal cost c), while the latter measures the firms ability to charge higher price for a given demand.

Therefore, trade liberalization (as a reduction in tariff) may generate an increase in the average technical efficiency but, on the other hand, tariff reduction shrinks domestic firms mark-up due to increased competition (pro-competitive effect). Given that our productivity measures include both terms, the statistical effect could cancel out.

A TBT and SPS

In order to guarantee the production and consumption of “safe” products without creating unnecessary barriers to trade, WTO countries defined a set of rules under which regulate both Technical Barriers to Trade (TBT) and Sanitary and Phyto-Sanitary (SPS).

TBT agreement aims at regulating technical standards or products requirements which are imposed by states with the objective of protecting human health or environment. However, the existence of many standards may make difficult the actives of exporting firms. TBT agreement aims to facilitate trade and to solve countries dispute on production standards. On the one hand, TBT agreement recognizes countries rights to adopt the standards they consider appropriate. On the other hand, the TBT agreement try to simplify exporting activities across the multitude of regulations. It is achieved in different ways. First, TBT agreement encourages countries to use international standards in order to uniform regulation. Second, countries should notify to a specific committee, TBT committee, the existing and future regulations on products standards.²⁵ According to the agreement, standards have to be fair and equitable²⁶, and any discriminatory practices between domestic produced and foreign good is discouraged.

Usually in response to notifications, countries may use the TBT Committee to discuss specific trade concerns (STCs) related to regulations or procedures of other countries that affect trade. Raised concerns are related to regulations that may be beyond the purpose of public safety and impose a discrimination between domestic and foreign producers. Concerns may be raised on both existing and forthcoming regulation (both should be notified to WTO).

Differently from TBT, **SPS agreement** aims to protect the safety of food and to prevent the spread of diseases among animals and plants. Morevoer, SPS measures cannot be used as protection for domestic producers. In particular such regulation cannot be used to discriminate between countries with similar prevailing conditions. In order to export, it is necessary to demonstrate that the exporting country achieve the same level of protection as in the importing country. Similarly to TBT, governments have to provide in advance notification on

²⁵Transparency is a fundamental point of TBT agreement. Notification, with establishment of enquiry points, and publication requirements are the three key points.

²⁶It is encouraged also the recognition of other countries' assessment procedures.

new or changed sanitary and phyto-sanitary regulations to SPS committee. As for TBT, WTO members can raise concerns on SPS to the SPS committee.

B Proofs Section3

Proof of Result 1. Substitute for $(c_D^A - s)^{k+2}$ from the (a) to get

$$L^B (c_D^B)^{k+2} = h - (\tau_A)^{-k} \left[h - L_B (\tau_B)^{-k} (c_D^B - s)^{k+2} \right]. \quad (15)$$

Whence, by differentiating,

$$dc_D^B/ds = -\beta/(\alpha - \beta) < 0. \quad (16)$$

where $\beta = (\tau_A^k \tau_B)^{-k} (c_D^B - s)^{k+1}$ and $\alpha = (c_D^B)^{k+1}$. Hence c_D^B decreases. Then, rewrite (A) as $(c_D^A - s)^{k+2} = (h/L^A) - (L_B/L^A) (\tau_B)^{-k} (c_D^B - s)^{k+2}$, so that:

$$c_D^A = s + (1/L^A)^{\frac{1}{k+1}} \left(h - L_B (\tau_B)^{-k} (c_D^B - s)^{k+2} \right)^{\frac{1}{k+1}}.$$

It is then easy to show that $dc_D^A/ds > 1$. Hence $c_D^A - s$, the *identity* cut off cost increases with s . Q.E.D.

Proof of Result 3. From (Bt) one has $L^B (c_D^B)^{k+2} = h - L^A (\tau_A)^{-k} (c_D^A - t)^{k+2}$, then (At) rewrites as

$$L^A (c_D^A)^{k+2} + (\tau_B)^{-k} \left[h - L^A (\tau_A)^{-k} (c_D^A - t)^{k+2} \right] = h$$

so that $\left[(c_D^A)^{k+1} - (\tau_B \tau_A)^{-k} (c_D^A - t)^{k+1} \right] dc_D^A + \left[(\tau_B \tau_A)^{-k} (c_D^A - t)^{k+1} \right] dt = 0$.

And $\frac{dc_D^A}{dt} = -\frac{(\tau_B \tau_A)^{-k} (c_D^A - t)^{k+1}}{(c_D^A)^{k+1} - (\tau_B \tau_A)^{-k} (c_D^A - t)^{k+1}} < 0$ since the denominator is positive. Q.E.D.

Proof of Result 4. An increase in the tariff is equivalent to a decrease in ρ_A hence look at $sign[-\frac{d}{dt}(G(c_D^B/\tau_B))]$ as equivalent to $sign[-\frac{d}{d\rho_A}(G(c_D^B/\tau_B))] = sign\left[-\frac{d}{d\rho_A}(c_D^B)\right] = (+)$ while $sign[-\frac{d}{d\rho_A}(G(c_D^A))] = (-)$ hence the numerator in $G(c_D^B/\tau_B)/G(c_D^A)$ increases while the denominator decreases. Q.E.D.

Proof of Lemma 2. From (BBb) one obtains (before the standard)

$$L^B (c_D^B)^{k+2} \left[\frac{3}{k+3} \left(1 - (\tau_A \tau_B)^{-k} \right) \right] = \gamma \phi (1 - \tau_A^{-k}). \quad (B0)$$

and from (BBa) one obtains (after the standard)

$$L^B(c_{D1}^B)^{k+2} \left[\frac{3}{k+3} \left(1 - \frac{k+3}{3} (\tau_{ATB})^{-k} \right) \right] = \gamma \phi (1 - \tau_A^{-k}). \quad (\text{Ba}).$$

Hence $c_{D1}^B \geq c_D^B$ if $1 - \frac{k+3}{3} (\tau_{ATB})^{-k} \leq 1 - (\tau_{ATB})^{-k}$, which is true given $(k+3)/3 > 1$. Q.E.D.

C NTM - Share of protected goods

We could compute the degree of protection by originated by NTM using the share of protected products within NACE rev2-2 digit sectors. First, we compute the share of protected products p by country of origin j for each sector s .

$$share_{sjt} = \frac{1}{N.Products(s)} \sum_{p(s)=1}^{P(s)} NTM_{jpt}^{EU} \quad (17)$$

Therefore, variable *share* includes the sum of all NTM (or TBT and SPS separately) concerns raised by country j for all products p within sector s .²⁷

In order to redistribute NTM across EU countries we define NTM protection index (PI) as

$$PI_{cst} = \sum_{j=1}^J share_{sjt} \frac{import_{js}^{c2002}}{import_{tot,s}^{c2002}} \quad (18)$$

where the weight measure the share of imports from country j in sector s for a CompNet country c .

[Figure 4 about here.]

D Additional Tables

[Table 12 about here.]

[Table 13 about here.]

[Table 14 about here.]

²⁷The numerator of the share is the amount of goods for which concerns have been raised against EU by country j in sector s .
